The National Sanitation Foundation's (NSF) Water Quality Index (WQI) is an empirical expression which integrates nine significant physical, chemical, and microbiological parameters of water quality into a single number to provide a uniform, consistent, and comprehensible term for measuring and reporting water quality.

To demonstrate the responsiveness of WQI to variations in water quality and to determine optimum frequencies for computing and reporting WQI, a comprehensive field sampling, laboratory analysis, and data management program was developed for applying WQI to selected sites on the Kansas River and its major tributaries. Seventeen parameters were measured (the nine in WQI and eight related parameters) on nearly 600 samples from 26 sites (14 main stem and 12 tributary). Parameters most responsible for quality variation in both main stem and tributary stations were identified by least squares regression. Results indicated that the NSF Water Quality Index (WQI) is an effective method for measuring and reporting overall quality variations in the Kansas River. (EPA)

ABSTRACT

The Water Quality Index (WQI) is an empirical expression which integrates nine significant physical, chemical, and microbiological parameters of water quality into a single number. It was developed by the National Sanitation Foundation (NSF) in response to the need for a uniform method of measuring and reporting water quality in consistent, comprehensible terms.

To meaningfully demonstrate the responsiveness of WQI to variations in water quality, and to determine optimum frequencies for computing and reporting WQI, a comprehensive field sampling, laboratory analysis, and data management program was systematically developed for applying WQI to selected sites on the Kansas River and its major tributaries. Nearly 600 samples from 26 sites - 14 main stem and 12 tributary - were included in the study. Seventeen parameters were measured in the laboratory - the nine in WQI and eight closely related parameters - to determine the validity of term substitution in the index expression. Parameters most responsible for quality variation in both main stem and tributary stations were identified by least squares regression. Results, expressed as WQI, indicated that the NSF water quality index is an effective method for measuring and reporting overall quality variations in the Kansas River. The operational methodology and results of the study are presented in detail in this report.

This report was submitted in fulfillment of Contract Number 68-01-0761 by The National Sanitation Foundation under the sponsorship of the Environmental Protection Agency. Work was completed as of January 1974.

ACKNOWLEDGMENTS

The outstanding cooperation of Jerome H. Svore, Regional Administrator, EPA Region VII, and Aleck Alexander, Project Officer, is gratefully acknowledged. Special appreciation is also expressed to EPA Region VII personnel who cooperated with the project staff by providing guidance and assistance in developing the study plan; providing laboratory space, equipment, and analytical services; collecting special samples; and entering the data to the STORET system.

The cooperation of Melville W. Gray, Chief Engineer and Director, Division of Environmental Health, Kansas State Department of Health and the assistance of members of his staff in selecting sampling locations and providing reports and equipment for use in the project is also greatly appreciated.

The project was directed by Dr. Nina I. McClelland. The field staff, headquartered at the EPA Region VII laboratory in Kansas City, Kansas, included Steven W. Weeks, chemist, in responsible charge of laboratory and field operations; Carroll L. Reynolds, chemist; Joyce E. Thale, microbiologist; and Larry M. Pope and Bill W. Brown, sample collectors. Dr. Rolf A. Deininger and Jurate M. Landwehr served as consultants to the project for designing the sampling program and processing data through the Michigan terminal system at the University of Michigan.

SECTION I

CONCLUSIONS

To insure continued public and private support for water quality improvement programs, a uniform, comprehensible format must be adopted for measuring and reporting progress - or lack of progress - in attaining current and future program objectives. Through widespread application of the water quality index (WQI), developed and applied by the National Sanitation Foundation (NSF), a specific, simplistic method is available for quantitative, consistent practice in measuring and reporting water quality. *It is emphasized that WQI is a management and general administrative tool intended for use in communicating water quality information to the lay public and to legislative decision makers. It is not a complex predictive model for technical and scientific application.*

The WQI was applied to selected sites in the Kansas River and major tributaries through a comprehensive three month field sampling, laboratory testing, and data analysis program. Results of this project demonstrated that:

1) WQI is responsive to changes in water quality resulting from discharge of municipal and industrial waste effluents and agricultural runoff in the study area.
2) WQI can be used effectively in optimizing sampling frequencies.
3) Four specific parameters - BOD_5, turbidity, phosphates, and fecal coliforms - are responsible for more than 90% of the variation in quality, expressed as WQI, in

river and tributary stations included in this study. Although the same four parameters are indicated in main stream and tributary data, their order of relative importance varies.

4) Two sets of parameters are highly correlated in both main stem and tributary stations - suspended solids with turbidity, and total coliforms with fecal coliforms. Other parameters are not closely related and cannot logically be substituted in calculating WQI for the Kansas River.

5) WQI is an effective method for indicating and reporting overall quality and expressing quality trends in the study area.

SECTION II

RECOMMENDATIONS

1) Data acquired during this study should be expanded to include all seasons of the year. Changes in quality which occur as normal seasonal variations are not reflected in this report as a result of the limited period of performance. A program should be implemented for applying WQI as a continuing water quality management tool throughout Region VII.

2) Comprehensive planning for future water quality objectives in Region VII should include the use of WQI as an integral part of interpreting changes in the overall quality of streams in the Region and reporting these changes to the public.

3) An education/public information program should be developed in Region VII to acquaint water quality control administrators, legislative decision makers, and the public with the meaning and use of WQI in evaluating stream quality.

4) WQI should be adopted on a national level to provide a basis for uniform water quality management operations. It is strongly recommended that programs similar to the Region VII study be implemented at the earliest opportunity in at least three additional regions. These regions should be widely separated geographically to demonstrate that WQI is responsive to changes in quality without respect to location. Each of these demonstrations should include an education/public information component.

SECTION III

THE WATER QUALITY INDEX

Definition

By definition, the Water Quality Index (WQI) is a single numerical expression which reflects the composite influence of nine significant physical, chemical, and microbiological parameters of water quality. It was developed and field evaluated by the National Sanitation Foundation (NSF) to provide a uniform method for indicating and reporting the benefits - or lack of benefits - realized from billions of public and private dollars invested in stream quality improvement programs.

Rationale

The need for a water quality index is well documented. In January 1959 the Committee on National Water Policy of the Conference of State Sanitary Engineers (CSSE) proposed that an objective study be initiated to develop a uniform method for indicating water quality. As a result of this action, the CSSE Committee and the Conference of State and Interstate Water Pollution Control Administrators (CSIWPCA) began developing criteria for demonstrating the progress of water pollution control programs, but nothing tangible emerged from this effort.

In 1965 the Environmental Pollution Panel of the President's Science Advisory Committee recommended that the federal government stimulate development of an index of chemical pollution, which would "allow us to follow many important changes in general water quality."(1)

The Environmental Study Group of the National Academy of Science proposed that various environmental indices, including "water purity" be developed and weighted into an overall Environmental Quality Index (2), a concept supported in a report to the Senate Committee on Public Works (3).

In its third annual report, the President's Council on Environmental Quality stated that, "Accurate and timely information on status and trends in the environment is necessary to shape sound public policy and to implement environmental quality programs efficiently. Further, the American people are entitled to know whether the public and private money being spent to protect the environment returns a commensurate improvement in environmental quality."(4)

The Honorable Russell E. Train, in addressing the National Conference on Managing the Environment, said "*Accurate and timely information on the status of the environment is necessary to shape sound public policy and to implement environmental quality programs efficiently. It is virtually impossible to develop effective programs and to monitor their implementation without good monitoring data. Very detailed data are necessary for certain types of planning and enforcement. For top management and general public policy development, monitoring data must be shaped into easy-to-understand indices that aggregate data into understandable forms. I am convinced that much more effort must be placed on the development of better monitoring systems and indices than we have in the past. Failure to do so will result in sub-optimum achievement of goals at much greater expense.*"(5)

These statements and recommendations are consistent with stated objectives for the NSF Water Quality Index, to:

1) Make available a tool for dependably treating water quality data and presenting them as a single numerical index, and
2) Promote utilization of a process for effectively communicating water quality conditions to all concerned.

Methodology

Development of WQI was undertaken by NSF as an unsponsored project. The basic methodology attempted to incorporate many aspects of DELPHI (6), an opinion research technique developed by the Rand Corporation. Individual judgements of a large panel of experts were integrated to produce a group decision. Through controlled feedback, each panelist was given the opportunity to compare his individual response with that of the group, and to change his response to more nearly conform with the group if he considered it desirable to do so.

A panel of 142 persons with expertise in water quality management was carefully selected for this study. Wide geographical distribution and diverse specialties - regulatory responsibility (federal, interstate, state, territorial, and regional), local public utilities management, consulting, and teaching - were represented. The panelists received a series of mailed questionnaires.

In the first questionnaire, the respondents were asked to consider the 35 parameters, shown in Table 1, for possible inclusion in a water quality index. Opportunity was provided to include additional parameters. Each parameter was to be designated according to one of the following categories: "do not include," "undecided," or "include."

Table 1. PARAMETERS CONSIDERED FOR WQI IN QUESTIONNAIRE NO. 1

Parameter
Dissolved oxygen
Fecal coliforms
pH
Biochemical oxygen demand (5-day)
Coliform organisms

Sodium and potassium
Acidity
Bicarbonate
Magnesium
Aluminum
Silica

Respondents were asked to rate only those parameters marked "include," according to their significance to overall water quality. This rating was done on a scale of "1" (highest relative significance) to "5" (lowest relative significance). Of the total panel of 142 members, 102 respondents (72%) completed and returned the first questionnaire; however, of these, only 94 were returned in time to be included in the second round.

The second mailing included a computer printout of results from the first questionnaire. Respondents were instructed to note their individual responses for each parameter and compare them with those of the entire group. In view of this feedback information, respondents were then asked to review their original judgements and modify them if they wished. The intent was to gain greater convergence of opinion concerning how the various parameters rated with respect to their effect on overall water quality. (However, there was little change in the significance ratings expressed in Questionnaire No. 2 when compared with the initial round.)

Nine additional parameters, added to the first questionnaire by several respondents, were introduced for group consideration in the second questionnaire: chromium (hexavalent), total organic carbon, cyanides, conductivity, lead, arsenic, cadmium, selenium, and zinc. In addition, panelists were asked to designate not more than 15 parameters, which they considered to be the "most important" for inclusion in a water quality index. The complete list of parameters was presented, arranged in decreasing order of significance as determined by the average rating of the entire group from Questionnaire No. 1. Of 94 respondents receiving the second questionnaire, 77 completed and returned it for an 82%

response rate. Utilizing expert opinion derived from initial rounds of the study, 11 parameters, or groups of parameters, were listed for further consideration.

In Questionnaire No. 3, respondents were asked to assign values for the variation in level of water quality produced by different levels of the nine individual parameters. This was accomplished by utilizing a series of graphs. Levels of "water quality" from 0 to 100 were indicated on the ordinate, and various levels (or strengths) of the particular parameter were arranged along the abscissa.

The respondents were asked to draw a curve which, in their judgement, represented the variation of water quality produced by the various possible measurements of each respective parameter. "Judgements" of all panelists were then combined to produce a set of "average curves" - one for each parameter. A complete set of curves is included as Appendix A of this report.

Special procedures seemed necessary for "pesticides" and "toxic elements," two "groups of parameters," and the respondents were asked to evaluate these. For pesticides it was proposed that "if the total content of detected pesticides (of all types) exceeds 0.1 mg/l (100 ppb), the water be automatically registered at zero, the lowest value on the water quality index scale." The suggested procedure for including "toxic elements" in the WQI "would be to set a critical upper limit for the presence of each element. If any toxic element exceeded its assigned upper limit, the water quality index would automatically register as zero." The maximum permissable levels for toxic elements contained in the current Drinking Water Standards (7) were proposed as those to be observed. The panelists agreed with this procedure for handling each of the groups of parameters.

The third mailing also sought information which contributed to the formation of "parameter weightings" in a final numerical expression. Thus, respondents were asked to compare relative overall water quality, using a scale of "1" (highest relative value) to "5" (lowest relative value). This operation differed from the initial rating of significance (Questionnaire No. 1) in that now only the final 11 parameters (or groups) were being considered. From these data, weightings were derived for each parameter included in the final WQI, according to the following procedure, summarized in Table 2.

1) Arithmetic means were calculated for the significance ratings returned for all parameters (except "pesticides" and "toxic elements").
2) Ratings were converted into weights by assigning a "temporary weight" of 1.0 to the parameter which received the highest significance rating; i.e., dissolved oxygen.
3) To preserve the ordering and relative ratios returned by the panelists, other temporary weights were obtained by dividing each individual mean rating into the highest rating.
4) Each "temporary weight" was then divided by the sum of all weights to obtain the final weights, w_i.

Table 2. SIGNIFICANCE RATINGS AND WEIGHTS FOR NINE PARAMETERS INCLUDED IN THE WQI

Parameters	Mean of all significance ratings returned by respondents	Temporary Weights	Final Weights
Dissolved Oxygen	1.4	1.0	0.17
Fecal Coliform Density	1.5	0.9	0.16
pH	2.1	0.7	0.11
Biochemical Oxygen Demand (5-day)	2.3	0.6	0.11
Nitrates	2.4	0.6	0.10
Phosphates	2.4	0.6	0.10
Temperature	2.4	0.6	0.10
Turbidity	2.9	0.5	0.08
Total Solids	3.2	0.4	0.07
		Total = Σ =	1.00

With parameter selection, quality curves, and relative parameter significance determined, the project staff proposed an additive expression for WQI:

$$WQI = \sum_{i=1}^{n} w_i q_i \qquad (1)$$

where WQI = the Water Quality Index, a number between 0 and 100 (theoretical),

q_i = the quality of the ith parameter, a number between 0 and 100, (read from the quality curves),

w_i = the unit weight of the ith parameter, a number between 0 and 0.17, and

n = the number of parameters.

In the WQI expression (Equation 1), $n = 9$ and includes:

- dissolved oxygen (DO), expressed as percent saturation
- fecal coliform density (FC), no./100 ml
- pH
- nitrates (NO_3), mg/l NO_3-N
- phosphates (PO_4), mg/l PO_4-P
- 5 day biochemical oxygen demand (BOD_5), mg/l
- temperature (T), °C departure from equilibrium*
- total solids (TS), mg/l, and
- turbidity, JTU (Jackson turbidity units)

*"Equilibrium" temperature is defined as that which is known to occur without the influence of heated or cooled discharge. In field application of WQI, two temperatures are taken:

one at the sampling site and one at some point upstream where heated or cooled discharge is known to be absent.

For samples from stations known to include pesticides or toxic elements, laboratory analysis of these constituents is required. When any level exceeds its maximum permissible limit, the index is automatically "zero."

Field Evaluation

Progress in developing WQI was first reported in a paper presented at the National Symposium on Data and Instrumentation for Water Quality Management, held in Madison, Wisconsin in July 1970 (8). Consistent with the concern that WQI be used responsibly, data from the quality curves (q_i) were not made available in this presentation. In response to requests for q_i data, NSF proposed that field application of WQI be undertaken as a coordinated effort. As a result, water quality management agencies (listed in Table 3) reported laboratory data to NSF from routine surveillance programs at more than 80 sites for periods up to 15 months. Again, this activity was entirely unsponsored. Site selection and sampling frequency were, in general, a function of availability of staff and fiscal resources within the participating agency. Data for the nine parameters in WQI were reported monthly; WQI's were calculated at NSF and returned to each participant.

A wide variety of quality characteristics were reflected in the data. Samples were taken from clean, upper reaches of

small streams, downstream from municipal wastewater treatment plants and points of industrial waste discharge, and lakes with seasonally diverse population densities. Results of the study showed clearly that quality variations are consistent with - and can be reported by - changes in WQI. They illustrated dramatically the fallacy of reporting quality variations in terms of changes in single parameter values. For example, at one station in Pennyslvania, downstream from two overloaded package wastewater treatment plants, least squares regression analysis of the data from 40 samples taken during the period July 1971 to August 1972 established that approximately 87% of the variation in WQI (R^2=0.8695) was determined by DO, BOD_5, pH, and total solids. At a station further downstream, just below the discharge from a mine pump, 92% (R^2=0.9169) of the WQI was determined by fecal coliform density, pH, and phosphates.

Quality profiles from three stations on a Michigan stream with recreational lakes scattered throughout the area reflected changes attributed to high density vacation populations. Flow patterns and mixing characteristics of treated wastewater effluent from a large city in Michigan were observed by plotting WQI values from stations on both sides of the receiving stream, above and below the treatment plant. These data are described in detail in a paper presented at the ASCE National Meeting on Water Resources Engineering (9), and in the final report prepared for each participant in the study (10).

Further Efforts to Evaluate WQI

Despite the apparent responsiveness of WQI to changes in water quality conditions, analysis of data from the field study suggested that the additive WQI lacked sensitivity in adequately reflecting the effect of a single low value parameter on overall water quality. Initially, the additive model was selected because it is conceptually simple, easy to calculate, and entirely reproducible. O'Connor noted that, "the additive model is a good choice when all parameters are within a reasonable range, but a multiplicative form is more sensitive to discontinuities in overall quality which may result with zero or poor quality in any parametric dimension."(11)

As a result, a multiplicative form of WQI was proposed (9):

$$WQI(M) = \prod_{i=1}^{n} q_i^{w_i} \qquad (2)$$

where WQI(M) = the multiplicative water quality index, a number between 0 and 100 (theoretical),

q_i = the quality of the ith parameter, a number between 0 and 100,

w_i = the unit weight of the ith parameter, a number between 0 and 0.17, and

n = the number of parameters.

To determine relative merits of adopting the additive WQI (WQI(A)) versus WQI(M) historical data for both "good" and "poor" quality stream conditions were accessed from STORET. WQI(A) and WQI(M) were calculated for all data and differences in the two values evaluated with respect to physical conditions known to exist at each reported site. Again, a wide variety of quality conditions were considered: upstream and downstream from refineries, steel mills, and municipal wastewater treatment plants. Data influenced by industrial wastes were significantly different when reported as WQI(A) versus WQI(M). As expected, WQI(M) was significantly more sensitive to the effect of a single bad parameter.

In addition to evaluating historical data, a questionnaire was mailed to 160 water quality management experts - more than 70 who participated in developing WQI, and others assumed to be new to the concept. The questionnaire was designed to determine, 1) how water quality ratings assigned by the experts related to WQI(A) versus WQI(M), and 2) whether or not original group judgement differed significantly from the opinions of other water quality experts.

Values for each of the nine WQI parameters in 20 actual stream samples - data from the Kansas study, the initial evaluation of WQI in Pennsylvania, Michigan, etc., and data accessed from STORET - were included in the questionnaire. The experts were asked to review the data for each individual sample and return both a numerical (0 to 100) and a verbal ("excellent," "good," "medium," "bad," or "very bad") rating which, in their judgement, described the quality of that sample.

More than 100 responses were returned, with 30 from the original group. Results of the survey to date indicate that:

1) Calculation of WQI by the additive model produces a number which averages 10 to 15 WQI units higher than experts judgementally rate the same water. The difference is greatest at the low end of the scale.

2) Calculation of WQI by the multiplicative model produces a number which averages 6 WQI units different, distributed above and below the experts' judgemental ratings.
3) There is no significant difference between the way original and new expert panelists rate water quality.

Although results of this survey are not yet complete, it is clear that the multiplicative WQI is closely related to expert judgement of water quality conditions. NOTE: *Because this report was completed prior to the survey, data in tables and figures are reported principally as WQI(A); however, WQI(M) values have been added to the tables in Appendix V, and plotted, for purposes of comparison, in Figure 3, 5, and 7.*

Questionnaire responses differed widely with regard to verbal ratings. A feedback questionnaire, to be mailed in the near future, will permit each panelist to review his response with respect to group judgement, and attempt to better define what the expert calls "good" or "bad" water quality.

SECTION IV

PROJECT DESCRIPTION

Objectives

Principal objectives of this project were to:

1) Apply WQI to selected sites in the Kansas River Basin through a comprehensive field sampling and laboratory analysis program, and
2) Evaluate the effectiveness and utility of WQI as an indicator of water quality variations.

Secondary objectives included determining optimum frequencies for sampling, computing, and reporting WQI.

Study Area

The main stem of the Kansas River originates at the confluence of the Republican and Smoky Hill Rivers, east of Junction City, and empties into the Missouri River 170 miles to the east at Kansas City. It is a wide, shallow river of moderate velocity with a shifting sand bottom. In terms of flow, it is the largest stream in Kansas.

Treated municipal wastes from more than 40 cities and towns ranging in population from 106 to 123,000, and effluents from at least 20 small wastewater treatment plants serving restaurants, mobile home parks, high schools, etc. are discharged to the Kansas River (12). The largest city, Kansas City, is heavily industrial; Topeka and Lawrence are characterized by light industry (principally food and kindred products, printing and publishing, fabricated metal products, and chemical processing). Other portions of the study area are essentially rural-agricultural, with river valleys commonly devoted to truck farming, and hilly areas, to pasturelands.

Selection of this area for application of WQI was a direct result of the high level of interest which water quality administrators in the area continue to express for the index concept in general, and WQI in particular. Administrative and technical staffs from EPA Region VII and the Kansas Department of Health contributed extensively to planning and conducting the project.

Sampling Sites

Twenty-six sites between Junction City and Kansas City - 14 on the Kansas River and 12 on major tributaries - were sampled for this study. Routine surveillance sites and stations from previous special studies were included. Intermediate sites were added when long distances occurred between the regular stations.

Sampling locations are listed in Table 4 and shown schematically in Figure 1. It is apparent from Figure 1 that flow in the study area is affected by a number of large impoundments, constructed for flood control, water supply, conservation, augmentation of flow for downstream uses, and recreation. Sampling was limited to sites downstream from the reservoirs.

Sampling Scheme

In designing the sampling program, a principal concern was to

Figure 1. Schematic illustration of sampling sites in Kansas River application of WQI.

provide a sufficiently large data base to be statistically significant in the evaluation process. A uniform pattern was established for sampling nine main stem stations considered to be critical for reflecting quality variations (high frequency stations); five main stem and four tributary stations considered somewhat less critical (medium frequency stations); and eight tributary stations (low frequency stations). The high frequency stations were sampled every other day; medium frequency stations, every fourth day. Sampling times for these stations were coincident with every second sample of the high frequency series.

Low frequency stations were sampled every eighth day, with sampling times coincident with every second sample in the medium frequency series, and every fourth sample in the high frequency series. One extra set of the low frequency samples was included in the schedule to compensate for the period when no low frequency samples would be collected if the every eighth day algorithm were strictly observed.

The overall sampling scheme, shown in Appendix B, is summarized as follows:

11 days, 26 stations (9+9+8) = 286 samples
8 days, 18 stations (9+9) = 144 samples
18 days, 9 stations = 162 samples
TOTAL 592 samples

The desirability of reflecting day to day variation was also considered in designing the sampling schedule. Sampling every second, fourth, or eighth day over an eight week period insured that at least one sample would be taken from each station on each day of the week. Variations which could be attributed to morning versus afternoon sampling times were considered by varying the direction of sampling; i.e., east to west or west to east, according to a predetermined pattern.

To optimize mileage logged for sampling, two sample collectors worked on the project. One, based in Kansas City, routinely sampled stations numbered 1 through 12; the other, based in Topeka, sampled stations 13 through 26, always in numerical order; e.g., 1 through 12 or 12 through 1. On high frequency sampling days, one man collected all nine samples. The Topeka-based collector worked on "west to east days," and the Kansas City-based collector worked on "east to west days." Time of travel for sample collectors ranged from five to eight hours in accordance with the predetermined daily schedule.

SECTION V

EXPERIMENTAL

Sample Collection and Preparation

Samples were collected from the downstream side of bridges, approximately midway across the stream and from a depth of two feet (except when river staging was too low to permit sampling at this depth). Bacteriological samples were collected in sterile bottles and iced for transport to the EPA Region VII laboratory in Kansas City, Kansas, which served as project headquarters. Samples for physical and chemical analyses were collected with an APHA-type DO sampler, dropped three times at each station. One, 300 ml BOD bottle was filled in the sampler, fixed in the field, and returned to the laboratory in a dark box for measurement of DO by the Winkler method. Excess sample was placed in two, one liter cubitainers and iced for transport. Temperature was measured in the field.

Sample preservation and maximum holding periods were in accordance with those described in Standard Methods (13) or the EPA Methods Manual (14). Maximum time lapse between collection and receipt of samples at the laboratory was six hours.

At the laboratory, DO titrations, BOD dilutions, and all bacteriological samples were processed immediately. Approximately 800 ml was removed from one cubitainer for the BOD test. The excess was preserved with mercuric chloride ($HgCl_2$, 1%) and refrigerated for subsequent analysis of nutrients (NO_3+NO_2, NH_3, and PO_4). A sample from the second cubitainer was placed in a four ounce bottle, preserved with HCl (2 ml), and refrigerated prior to shipping to Ann Arbor for measuring TOC. Excess sample was refrigerated overnight (approximately 12 hours) at 4°C. The following morning, it was warmed to 25°C, mixed by inversion, and used for immediate determination of pH, conductivity, and turbidity. The excess was again refrigerated for subsequent chloride, solids (total and suspended), and COD analyses. A schematic illustration of sample distribution and preparation is shown in Figure 2.

Methods

Seventeen parameters were measured in the laboratory - the nine in WQI and eight closely related parameters - to determine the validity of term substitution in the index expression. (The eight additional parameters included: suspended solids, chemical oxygen demand (COD), total organic carbon (TOC), total coliform density, and fecal streptococci.) Analytical procedures were performed in accordance with Standard Methods (13) or the EPA Methods Manual (14). The specific methods used in this study are shown in Table 5.

Quality control procedures were employed routinely throughout the laboratory phase of this project. EPA analytical reference standards for all parameters were included at random with routine analyses. Instruments were standardized regularly before and during each use. In general, quality control procedures were performed in accordance with the EPA Handbook for Water and Wastewater Laboratories (15).

NOTE: *All analytical data from this study have been entered into the EPA STORET system. They can be retrieved by using Code No. 117INDX and numbers of respective individual parameters, shown in Table 5.*

SECTION VI

RESULTS

WQI(A) and WQI(M) were calculated for all sampling days except October 6 when aliquots prepared for NO_3+NO_2 (and NH_3) were accidentally discarded. In all calculations, temperature, expressed as degrees C departure from equilibrium, was assumed to be zero. No effects of heated or cooled discharge were known to occur at any sampling station included in the study. Two temperatures were taken during the early sampling runs - one at the site and one upstream - to confirm this hypothesis.

Data for each of the 17 individual parameters and time of sampling are shown by station in Appendix C (Tables C-1 through C-26). Flow, provided by the U.S. Geological Survey from gauging stations in the study area, are also reported in tables in Appendix C. WQI(A), WQI(M), and quality ratings (q_i) for each parameter in WQI are reported by station in the tables (D-1 through D-26) in Appendix D. Note that temperature q_i is consistently reported as 94.9 as a result of assuming zero degrees departure from equilibrium for all samples.

Summary statistics for each variable in WQI(A), including the number of analyses (n), arithmetic mean, standard deviation, standard error of the mean, minimum, and maximum values are shown in Appendix E (Tables E-1 through E-26) for each individual station.

In Appendix F (Figures F-1 through F-26), WQI(A) is plotted versus time (date) of sampling for each station.

Water quality index profiles - WQI(A) versus distance - are shown in Appendix G (Figures G-1 through G-36). Note that distances (station locations) are approximate in this series of figures. River stations are connected by solid line; tributary WQI's are shown as individual points, not connected to the solid line. Numbers near the data points refer to flow, in cfs, recorded at USGS gauging stations at the time of sampling.

SECTION VII
DISCUSSION

Quality Variations

Deininger reported that values ±5 WQI are significantly different, and "WQI is probably sensitive down to a two point difference"(16). In discussing the data from this study variations ±5 WQI(A) or WQI(M) are assumed to be significant.

Mean values for WQI(A) and WQI(M) at all stations over the entire period of observation are plotted in Figure 3. Main stem stations are connected by a solid line and tributary stations are shown as isolated points, as described in the legend. From the data in Figure 3, it is apparent that quality in the main river showed no significant variation over the study period when expressed as mean WQI(A) (range 65-68), and varied only slightly as mean WQI(M) (range 51-58). The quality at Willard, Lawrence, and Paxico was significantly better than at Eudora or Topeka, and at Willard, it also exceeded the quality at the James Street station in Kansas City (as WQI(M)).

The greater range and sensitivity of WQI(M) is further illustrated in Figures 4 and 5 (mean, high, and low WQI(A) and WQI(M), respectively, for main river stations) and Figures 6 and 7 (mean, high, and low WQI(A) and WQI(M) for tributaries). The effect of one or two unusually "bad" parameters is apparent by visual comparison of the range of WQI values reported for the Delaware River (Figures 6 and 7). This was the "best" quality tributary over the period of observation. In the sample taken on November 13th, turbidity and fecal coliforms were unusually high - 140 JTU and 2900/100 ml, respectively. The highest turbidity level in any other Delaware

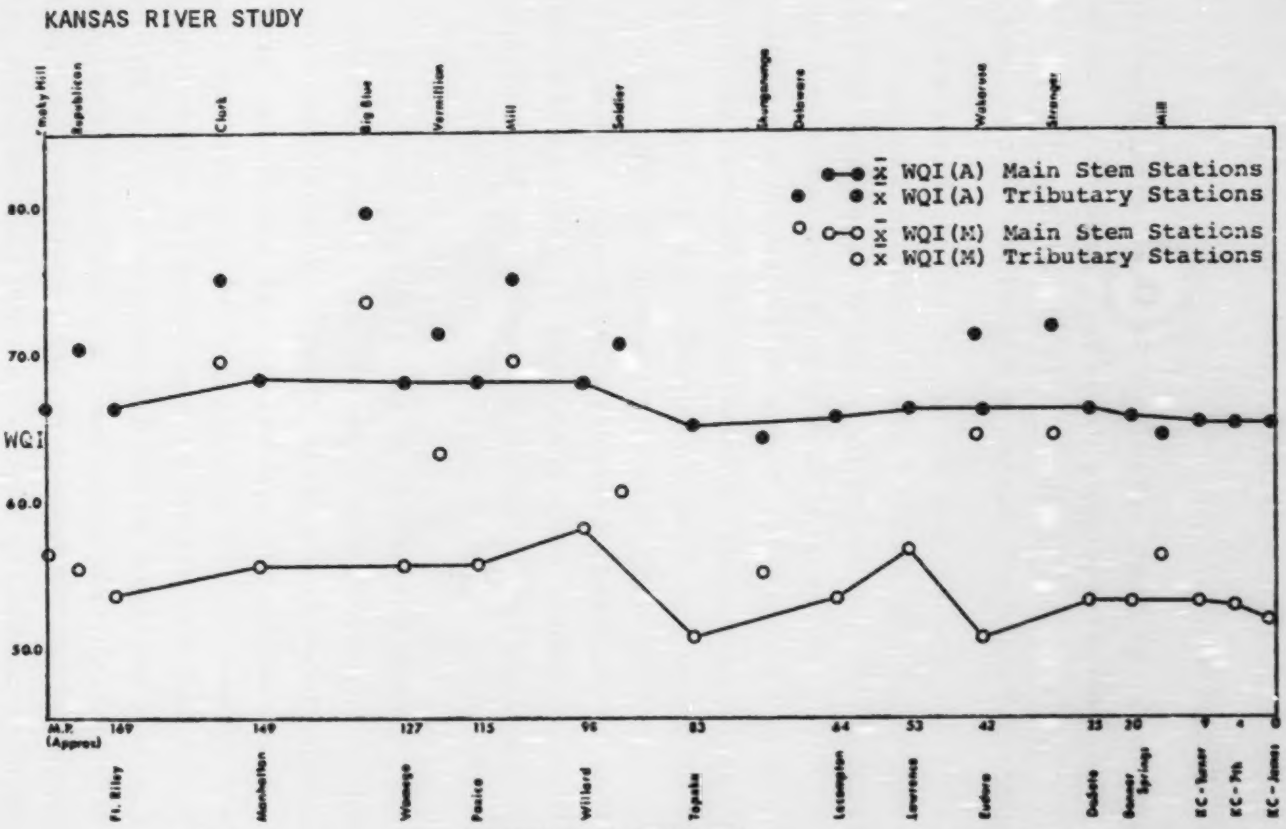

Figure 3. Mean values for WQI(A) and WQI(M) at all stations for entire observation period (09/26/72 - 12/07/72).

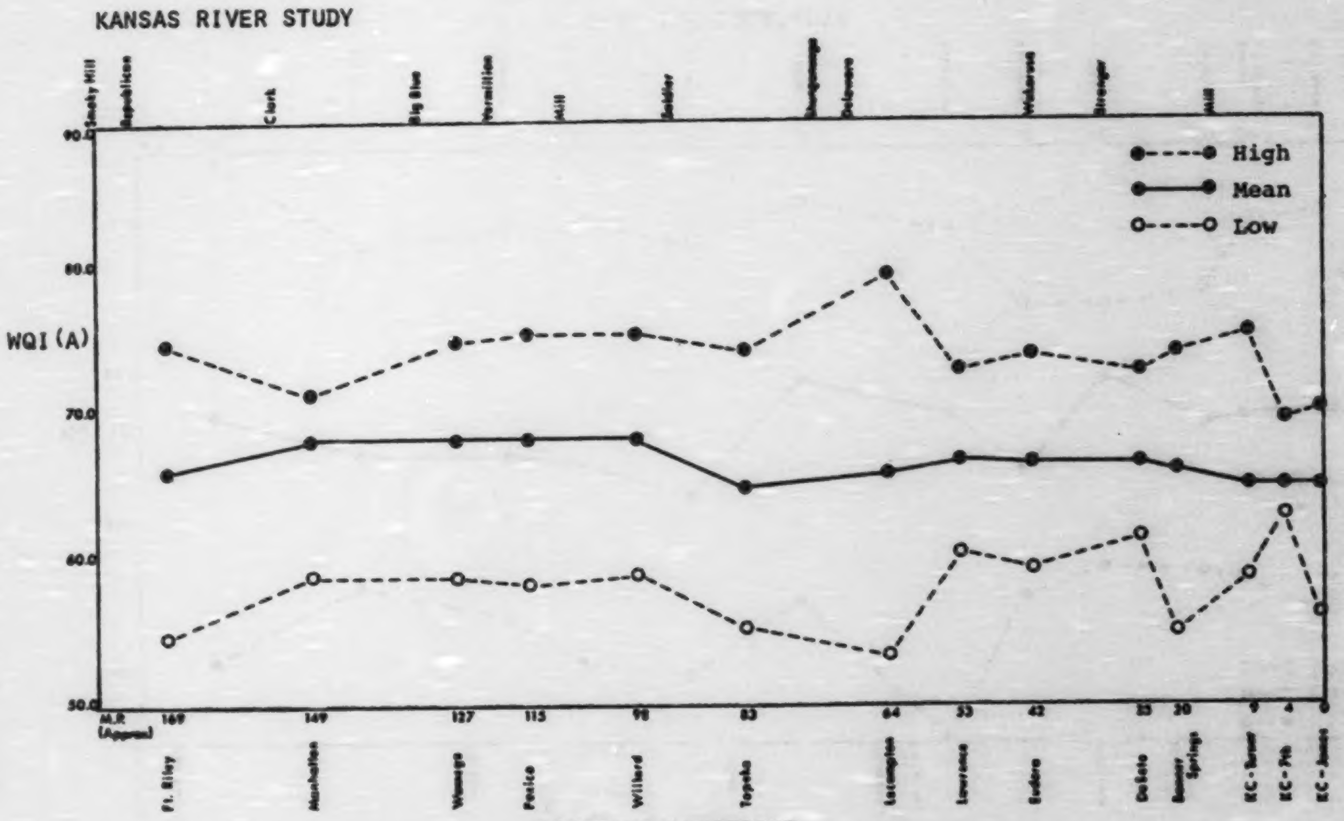

Figure 4. Mean, high, and low WQI(A) for Kansas River stations.

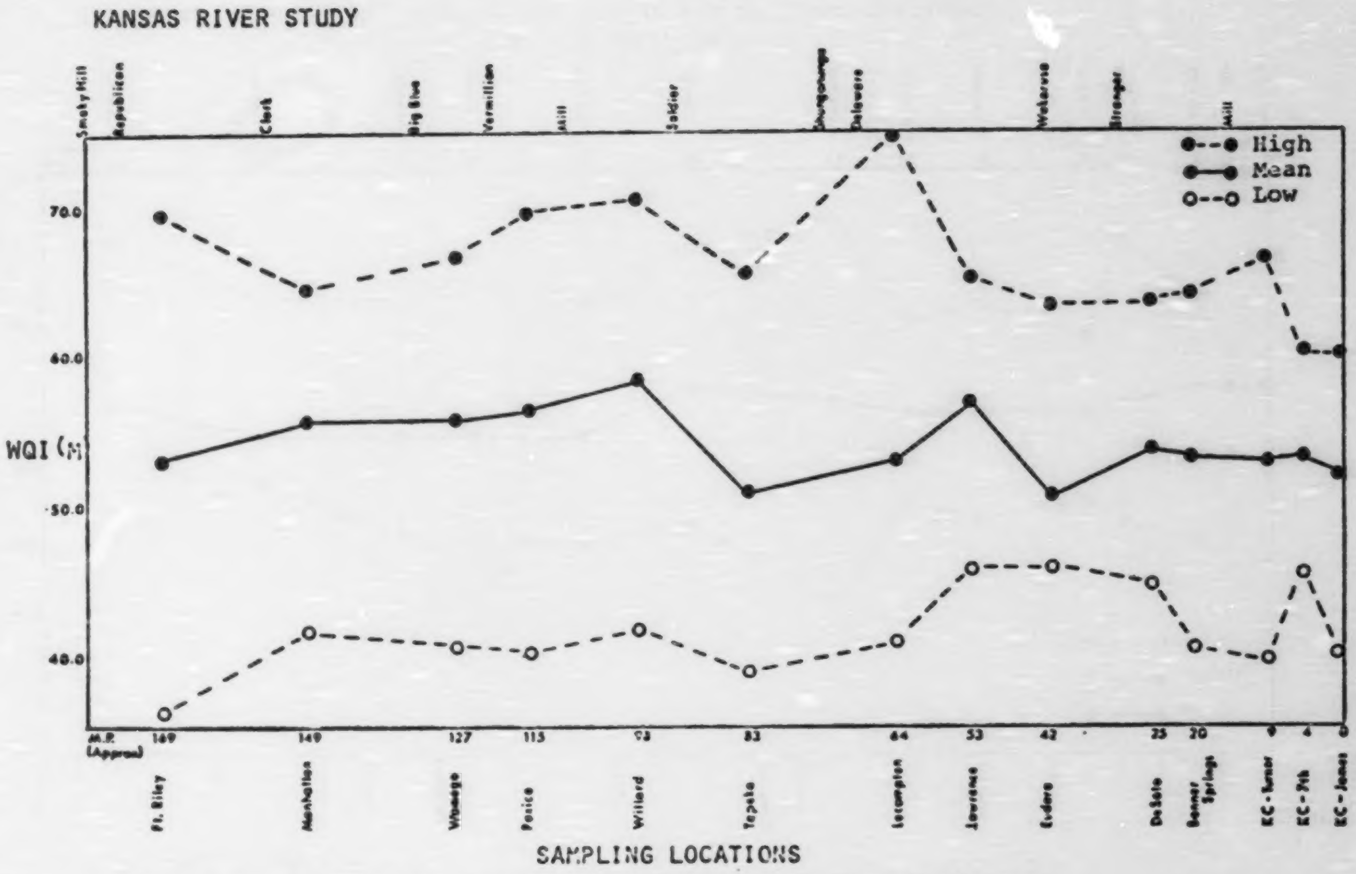

Figure 5. Mean, high, and low WQI(M) for Kansas River stations.

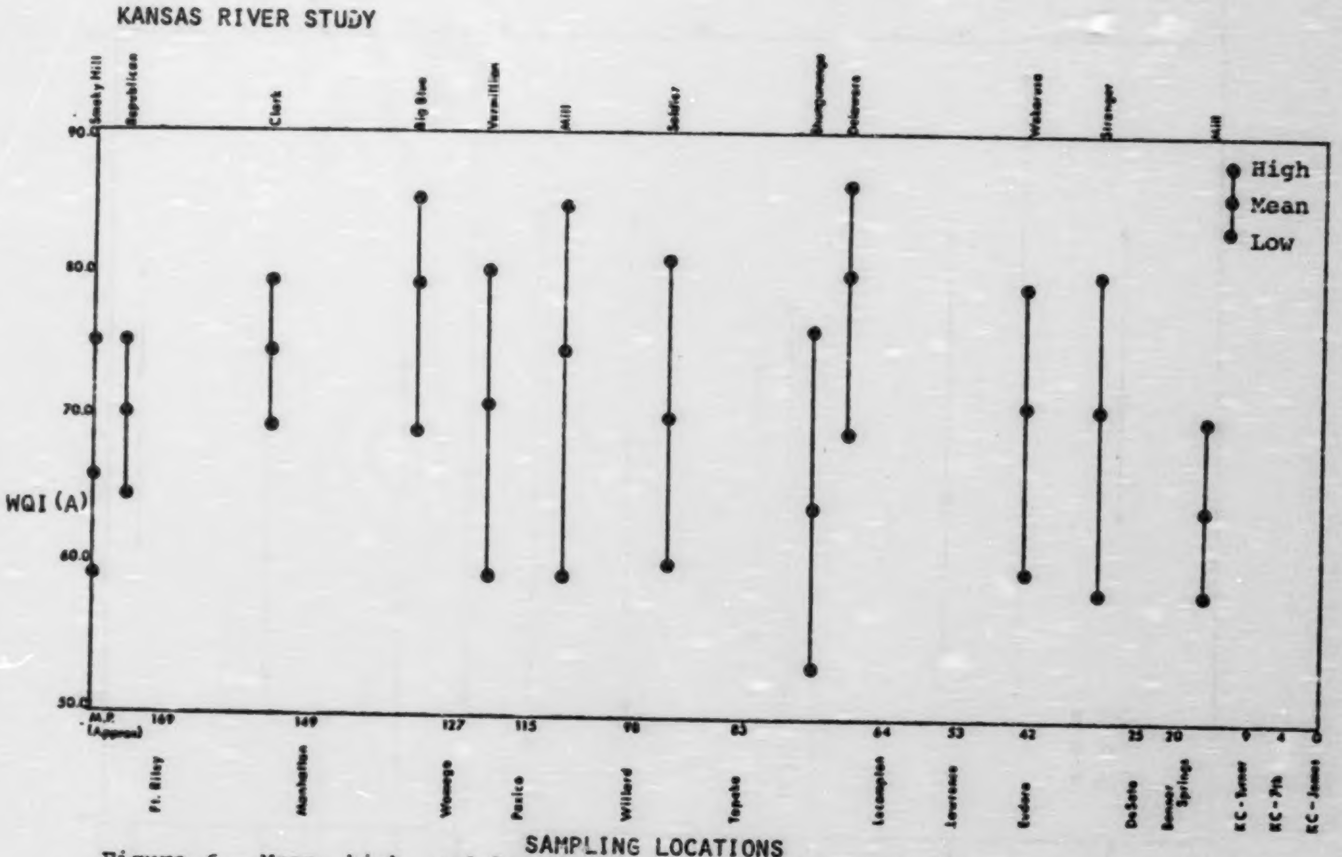

Figure 6. Mean, high, and low WQI(A) for tributary stations.

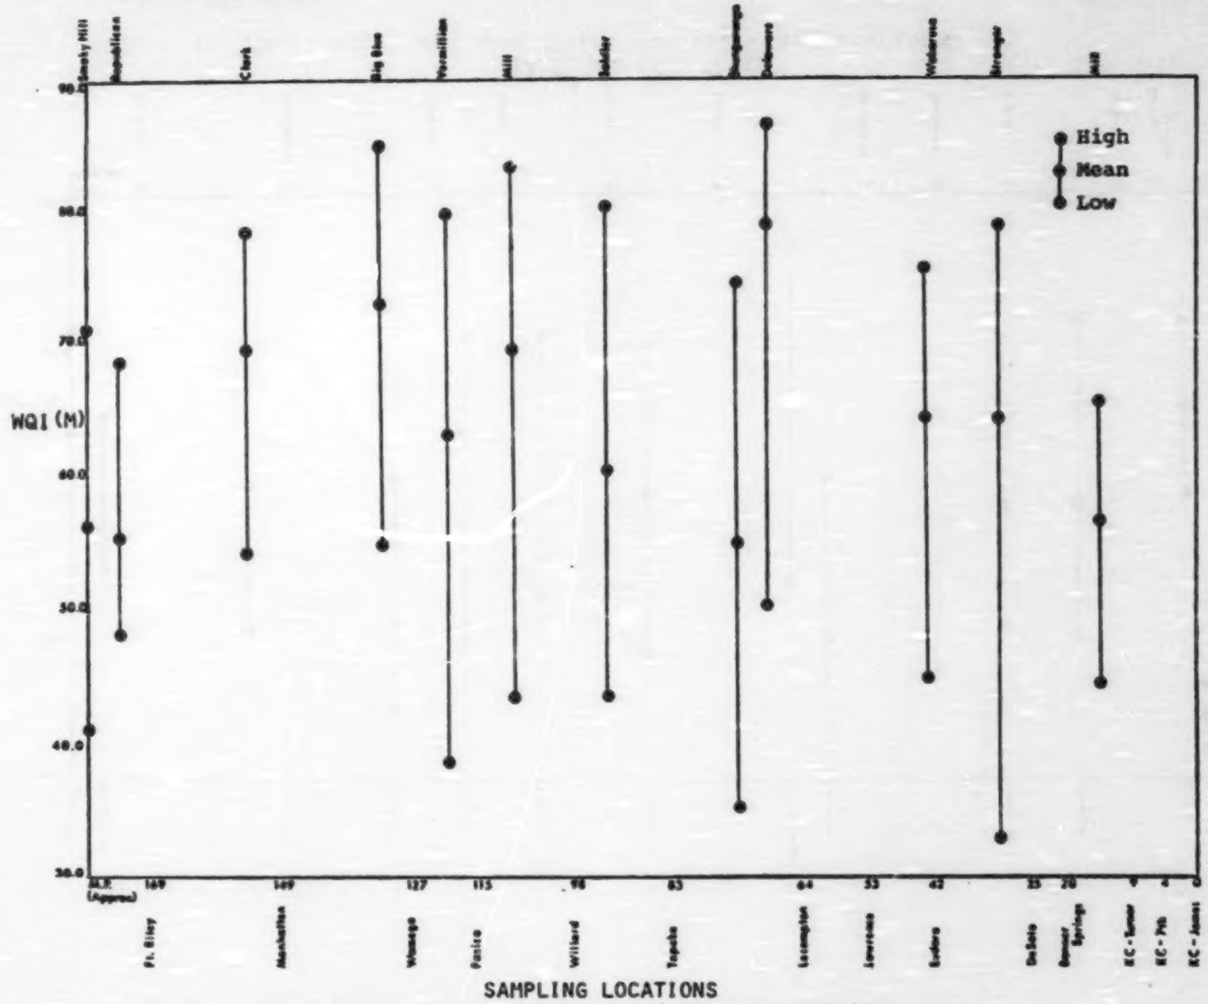

Figure 7. Mean, high, and low WQI(M) for tributary stations.

River sample was 40 JTU; the mean for all other samples was 15.5 (JTU) (Table C-12, Appendix C). Expressed as q_i, a turbidity of 140 JTU equals 5.00; a turbidity of 40 JTU equals 44.7 (Table D-12, Appendix D). Fecal coliform density in the Delaware on November 13th was 2900/100 ml. The mean of all other samples was 202/100 ml. Expressed as q_i, these values are 14.6 and 34.8, respectively. Other unusually high data for this sample are not included in the WQI expression; e.g., suspended solids and total coliforms. Comparison of the range of WQI values shown in Figures 6 and 7 for the Delaware River demonstrate the improved sensitivity of WQI(M) for treating unusually bad parameter values. The maximum is the same in both figures, the mean, only slightly less for WQI(M), but the low WQI(M) is significantly lower than the lowest WQI(A).

Data from Figures 3, 4, 5, 6, and 7 are summarized in Table 6. Willard, the "best quality" Kansas River station, is a small town (population 94) about midway between Paxico and Topeka. Small creeks discharge to the Kansas River between Paxico and Willard, but there is no reason to expect any of them to contribute significant pollutional loadings. The Willard location was sampled principally because of the long distance between Paxico and Topeka.

"Best" tributary quality was recorded from the Delaware and Big Blue Rivers, discharging from Perry and Tuttle Creek Reservoirs, respectively. Because reservoir retention provides time for self purification and sedimentation, the quality at these stations was expected to be consistently high.

"Poorest" quality in the main river occurred at the station near Eudora, just downstream from Lawrence, and at Topeka. "Poorest" quality in a tributary was observed in Shunganunga Creek. Quality variations at the Eudora station result

Table 6. SUMMARY OF WQI(A) AND WQI(M) FOR KANSAS RIVER AND TRIBUTARY STATIONS

	Kansas River Stations				Tributary Stations			
Observed Characteristic	Location	WQI(A) Mean / Range	Location	WQI(M) Mean / Range	Location	WQI(A) Mean / Range	Location	WQI(M) Mean / Range
Best Quality	No statistically significant difference in quality between stations at level of ±5 WQI(A)		Willard	58	Delaware Big Blue	81 79	Delaware Big Blue	78 73
Poorest Quality			Topeka Eudora	51 51	Shunganunga Mill Creek	64 64	Shunganunga	55
Most Variation	Lecompton	53-79	Lecompton	41-75	Mill Creek Stranger Creek	59-85 57-81	Stranger Creek	33-78
Least Variation	Kansas City @7th Street	63-69	Kansas City @7th Street	45-60	Republican River	65-76	Republican River	48-68

principally from municipal and separate industrial waste discharges in the Lawrence area. (Wastes from Eudora are discharged to the Wakarusa River which enters the Kansas just downstream from the Eudora station.) Lawrence discharges 4.57 mgd directly to the Kansas River from a primary plant treating a waste of 45,700 population equivalent, with contributions from at least nine industries including organic dyes and inks, blood, and various food processing wastes. Industrial wastes discharged directly to the Kansas River include: an electric utility (.01 mgd treated by extended aeration plus .43 mgd cooling water), an industrial and agricultural chemical company (500 gpm of untreated process wastes containing phosphates, suspended solids, and hexavalent chromium), and a paper and container board company (900 gpm of treated wastes containing suspended solids, sulfates, and organics with a mean BOD of 80 mg/l.

Topeka is the second largest city in the study area, and discharges both municipal and industrial wastes directly to the main river. The principal municipal wastewater treatment plant is located downstream from the Topeka sampling location and would not be expected to have an affect on quality at this point. A smaller plant (designed for 12,500 P.E. and loaded at approximately 1000 P.E.) upstream from the sampling location discharges its effluent along the north bank of the river and would likely not be well mixed with water in the river at the referenced sampling point. It may be reasonable to assume that either an unidentified direct industrial waste discharge or storm water from Topeka contributed to the relatively low mean WQI value observed at the Topeka location. Storm water discharge and effluents from the wastewater treatment plant serving Forbes Air Force Base may also contribute significantly to the observed mean WQI for Shunganunga Creek, which flows through the City of Topeka.

The main stem station with the widest range of reported WQI was at Lecompton, just downstream from the point where the Delaware River discharges to the Kansas, and downstream from Topeka. The Delaware contributes good quality flows to the Kansas with discharges from Perry Reservoir; however, it appears that the main river may be stratified at the Lecompton station and that the stratification line may change as a function of relative flows in the two streams. Thus samples collected from midstream may have been in different strata at various times of sampling. Least variation in main stream stations was observed in Kansas City at 7th Street.

NOTE: *From Table 6, it is apparent that characteristics observed at any sampling location were the same whether calculations were additive or multiplicative in format.*

Despite the brevity of the field phase of this study, quality in the Kansas River and its tributaries generally improved over the period of observation. Initial and final WQI(A) values for each sampling location are plotted in Figure 8. At a level of ±5 WQI units, all main river stations except Kansas City at 7th Street, DeSoto, Lawrence, and Ft. Riley, and all tributary stations except the Delaware River, Soldier Creek, and Clark Creek, showed significant improvement. This effect can likely be attributed to normal seasonal variation associated with the colder weather.

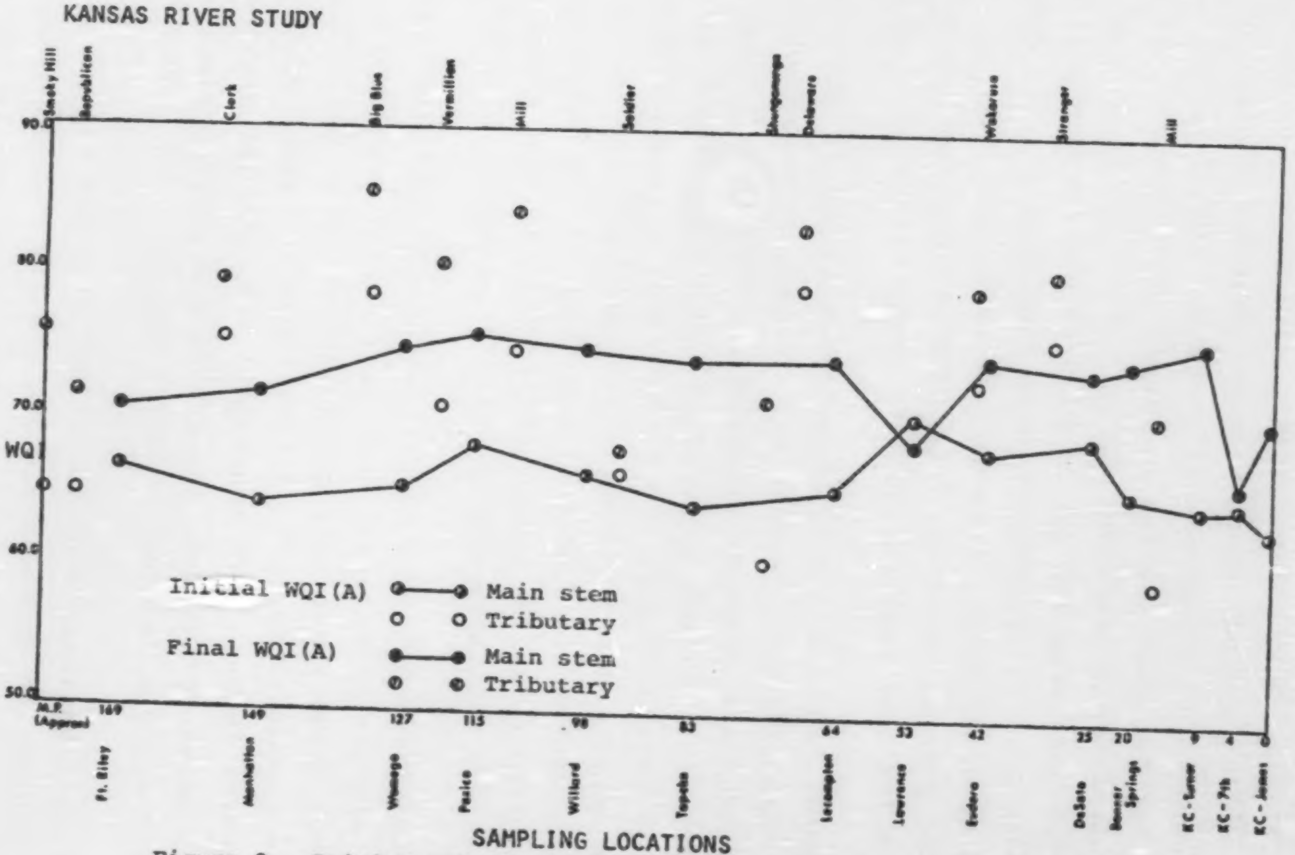

Figure 8. Initial and final WQI(A) values for all sampling stations.

Although no significant variation in quality expressed as mean WQI(A) is demonstrated in the main river over the entire sampling period, short term variations are apparent from the figures in Appendices F and G. WQI(A) versus time is plotted for each station in Figures F-1 through F-26 (Appendix F), and profiles, WQI(A) versus distance, are shown for each sampling day in Figures G-1 through G-36 (Appendix G). In Appendix G, main stem stations are connected by solid lines, tributary stations are shown as isolated points, and flow, from USGS gauging stations, by numbers (as cfs) near the quality designations.

In general, the quality of tributaries is better than that in the main stream (Appendix G); however, Mill and Shunganunga Creeks are frequent exceptions. (Two "Mill" Creek sampling stations are included in the study. These were on two separate creeks, one considerably east (upstream) of the other. Reference to "Mill Creek" quality in the previous statement relates to the creek to the east, near Kansas City.) Bridge construction near the Mill Creek station may have affected the data acquired at this location.

From the figures in Appendix F, it is apparent that quality in rivers and tributaries does vary between sampling periods, and that these variations can be expressed as WQI. This single number expression of nine important water quality parameters is much more meaningful than similar plots of single parameter values, and provides a sound basis for water quality management decision making.

Short term variations at individual stations are shown in the data plotted in Appendix F. The quality changed significantly (±5 WQI units) from sample to sample six times in the main river at Kansas City-James Street (10-14/16, 10-20/22, 10-22/24, 11-07/09, 11-11/13, 11-15/17), and nine times at

Lecompton (10-02/04, 11-11/13, 11-15/17, 11-19/21, 11-23/25, 11-27/29, 11-29/12-02, 12-02/03, 12-03/05). Lecompton was the high frequency station previously reported (Table 6) to be "most variable" on the main river. Most of the variation occurred late in the study. Every other sample from November 09-23, and every sample from November 23-December 05 was significantly different from the sample taken either just before - or just after -, or both. Four individual parameters - PO_4, total solids, turbidity, and BOD_5 - varied appreciably during this period.

Data from Kansas river stations at Topeka and Lecompton and from tributary stations discharging between these two main river stations - Soldier Creek (which receives industrial wastes from a rubber company), Shunganunga Creek, and the Delaware River - are plotted in Figure 9. Data only from days on which all stations were sampled are included. The upstream station, Topeka, is shown in the open circle, solid line format, and the downstream station, Lecompton, in the closed circle, solid line format. The ability of WQI to reflect the effect of tributary contributions on overall quality of the main stream is demonstrated in this figure. During the period 09-26 to 10-04, downstream quality was significantly altered by the relatively poor quality discharged from Shunganunga Creek. Flow in the creek was so low at the time of sampling on 10-04 that the sample depth was two inches (routinely two feet), thus temperature was high; percent DO saturation, low; fecal coliform density, high; etc. Flow in the main stream was also relatively low during this period, thus the apparent effect of the tributary contribution was dramatic. Downstream quality improved on 10-12, apparently as a result of rainfall that provided dilution, and the release of high quality water from Perry Reservoir, and peaked on 10-20 with good quality contributions from all tributary sources. Conversely,

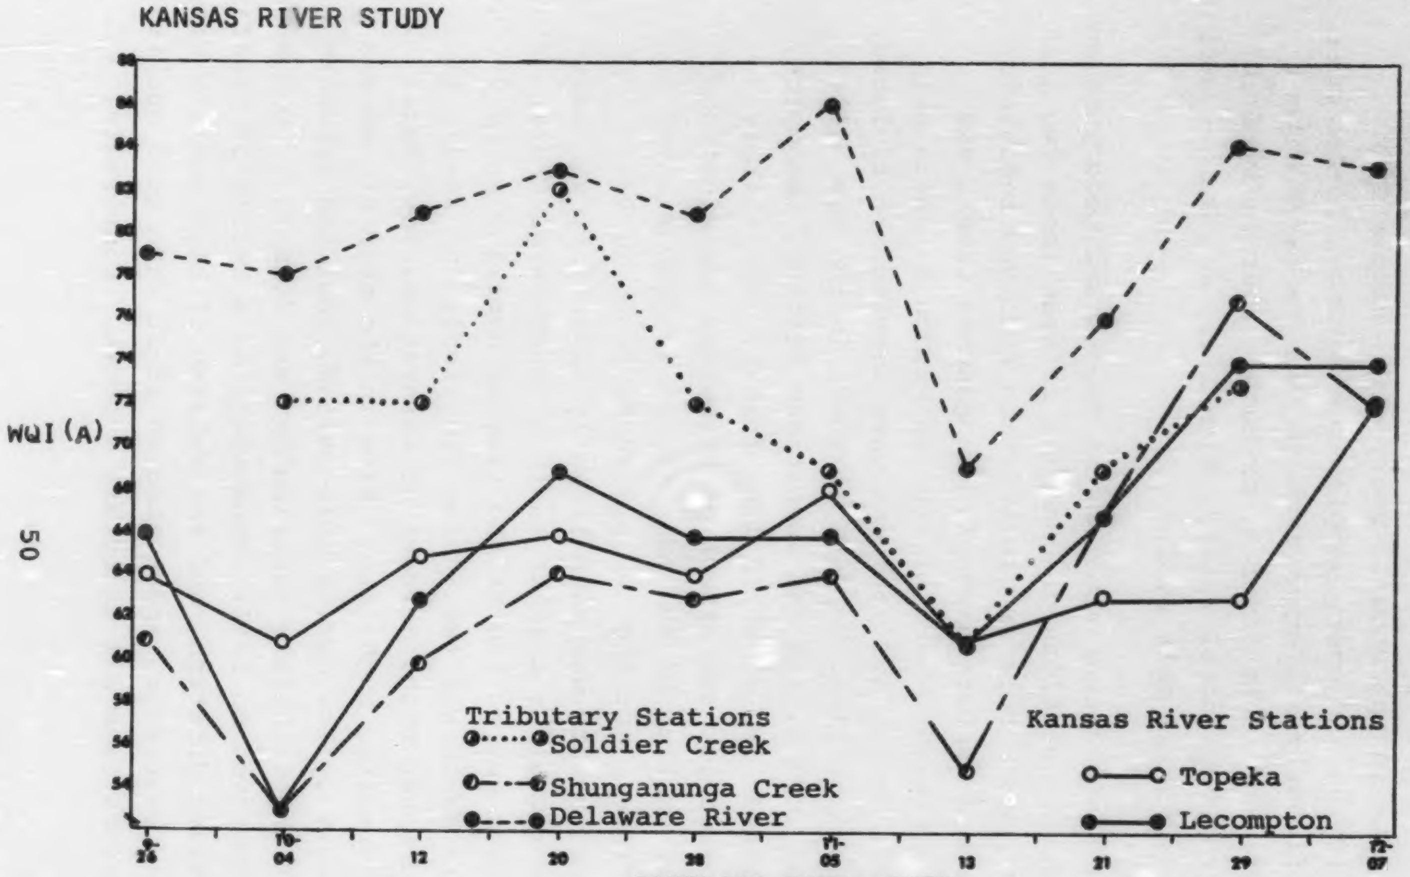

Figure 9. Effect, expressed as WQI(A), of three tributaries on quality in Kansas River at Topeka and Lecompton.

quality dropped in all the tributaries on 11-13, and downstream quality again reflected these changes. Flow on this date was relatively high at all stations - from 1800 cfs on 11-05 at Topeka to 4000 cfs on 11-13; 150 cfs on 11-05 on the Delaware River to 500 on 11-13; 40 cfs on Soldier Creek to 3000 cfs; and 2600 cfs to 5200 cfs at Lecompton. It would appear that these flows had a scouring effect on the streams which reflected in calculated values of WQI. Flows recorded for Topeka, the Delaware River, and Lecompton between the intervals shown in Figure 9 continued to increase, then became relatively consistent for Lecompton; e.g., 11-15, 12,000 cfs; 11-17, 10,000 cfs; 11-19, 9600 cfs; 11-21, 8000 cfs; 11-23, 7400 cfs; 11-25, 7400 cfs; 11-27, 7700 cfs (from Table C-11, Appendix C) - until peak quality was observed on 11-29. With some basic knowledge of the sampling sites, flow characteristics, etc., it is possible to explain the apparent trends in Figure 9, and to use this information to predict future effects of changes in quality at these locations. WQI provides an ideal method for presenting overall quality variations as a function of time and distance. No single parameter data could be used in achieving similar objectives.

Frequency of Sampling, Computing, and Reporting WQI

In determining optimum sampling frequency, "true mean" and "true standard deviation" were computed for the largest data base available; i.e., WQI values for the nine high frequency stations. For every station (i) in this group, there were thirty-seven WQI values [$W_{i,1}$, $W_{i,2}$, $W_{i,3}$..., $W_{i,37}$] which refer to every other sampling day (1, 3, 5, 7..., 37) during the study.

The data record was then divided in half by arranging the WQI's into two sets. Consecutive values in each set now refer to samples taken four days (d) apart; i.e.,

I	II
WQI_{d_1}	WQI_{d_2}
d_3	d_4
d_5	d_6
$\vdots$	$\vdots$
d_{37}	d_{36}

Mean (M_i, and M_{i_2}) and percent deviation (PD_i, and PD_{i_2}) from the mean were calculated for each of these two sets.

To estimate deviation from the true mean if samples were taken every fourth rather than every second day, average percent deviation was calculated. The steps are summarized as follows:

$$1)\quad [W_{i,1}, W_{i,2}, W_{i,3} \ldots, W_{i,37}] \rightarrow TM_i \text{ and } TSD_i \qquad (3)$$

where i = station 1, 2, 3,...9
W = $WQI_1 \ldots WQI_{37}$ at station i
TM = true mean
TSD = true standard deviation

$$2)\quad [W_{i,1}, W_{i,3}, W_{i,5} \ldots, W_{i,37}] \rightarrow M_{i,1} \rightarrow PD_{i,1}$$

$$= \frac{(TM_i - M_{i,1})}{TM_i} \times 100 \qquad (4)$$

and

$$[W_{i,2}, W_{i,4}, W_{i,6} \ldots, W_{i,36}] \rightarrow M_{i,2} \rightarrow PD_{i,2}$$

$$= \frac{(TM_i - M_{i,2})}{TM_i} \times 100 \quad (5)$$

3) $APD_i = PD_i = 1/2\ (PD_{i,1} + PD_{i,2}) \quad (6)$

This process was continued for three through 19 sets of sub records; i.e., percent deviation of mean WQI was estimated for samples taken every fourth, sixth, eighth. . . fortieth day versus the "true mean" experienced with sampling every second day. Using this approach, the lowest percent deviation from the true mean occurred for samples taken every sixth day for six of the nine stations.

For all nine stations, twenty-day sampling frequencies provided WQI values with less than (<) 2% average deviation from the mean. If this is sufficient accuracy for routine surveillance programs in the study area, the every twenty-day sampling scheme should be adopted. Results of this analysis are shown in Table 7.

The practice of calculating WQI each time data for all nine parameters are available is recommended. With calculators and computers generally available, calculation of WQI is a simple "next step" in processing water quality data. Hand calculation, though more tedious, is also manageable.

The optimum frequency for reporting WQI is a function of variations in data which may occur as a result of local

Table 7. SAMPLING FREQUENCY

Average % Deviation from "True Mean"

conditions. The duration of the field sampling phase of this study was too short to reflect seasonal variations, and improperly timed to be coincident with high temperature, low flow conditions. A firm recommendation for frequency of reporting WQI should be made only when these additional data are available for consideration. Review of statistical data (Appendix E) from the period of observation suggests that reporting only once every three months or more is sufficient to indicate water quality conditions during the fall months.

By applying least squares regression, four parameters were shown to account for more than 90% of the variance in WQI over the period of observation. Results of these analyses are summarized in Table 8. The summary is grouped to include 1) all data and 2) all main stem river stations. Although the same four parameters are indicated in both groups of data, variation in their relative importances is noted. By difference, it is apparent that fecal coliform density accounts for most of the variance in quality at tributary stations but is a considerably less important parameter at river stations. Although there is no adequate substitute for adopting a uniform method of reporting water quality, this information, when related to costs for laboratory analysis of each parameter, is useful in planning routine data acquisition programs. In reporting WQI all nine parameters in the expression must be measured. However, more frequent analysis of fewer parameters may be used to show intermittent trends in stream quality, particularly at critical locations.

Table 8. REGRESSION ANALYSIS OF WQI PARAMETERS BY FORWARD SELECTION

All Data (From Quality Ratings)		All River Stations (From q_i)

SECTION VIII

SPECIAL STUDIES

Parameter Correlations

In field application of WQI, the feasibility of parameter substitution is frequently discussed. To establish the effect of modifying parameters, as well as reducing the number of total parameters in the index expression, laboratory analysis in this study was extended to include 15 parameters for all samples, and 17 parameters on 11 predetermined sampling days. Analytical data for all samples included the following measurements:

- all nine parameters in WQI, plus
- conductivity, μmhos/cm
- suspended solids, mg/l
- ammonia, mg/l NH_3-N
- chlorides, mg/l
- total coliform density, #/100 ml
- fecal streptococci, #/100 ml

Analytical data for samples collected on 9-28, 10-6, 10-10, 10-18, 10-26, 11-3, 11-11, 11-15, 11-19, 11-27, and 12-5 included two additional parameters:

- chemical oxygen demand (COD), mg/l and
- total organic carbon (TOC), mg/l.

Correlation coefficients for eight selected pairs of parameters are shown in Table 9: total solids versus conductivity, total solids versus suspended solids, turbidity versus suspended solids, fecal coliforms versus total coliforms, and fecal coliforms versus fecal streptococci.

Table 9. CORRELATION COEFFICIENTS FOR SELECTED PARAMETERS

Parameters	All Data R @ 95. = .083 R @ 99. = .109	All River Stations R @ 95. = .094 R @ 99. = .123
Total solids versus Conductivity	.385	.456
Total solids versus Suspended solids	.742	.575
Turbidity versus Suspended solids	.932	.937
Fecal coliforms versus Total coliforms	.855	.849
Fecal coliforms versus Fecal streptococci	.165	.131

In each pair, the parameter in WQI is listed first; the related parameter follows.

Data are grouped to include all data, and all main river stations, with correlation coefficients expressed at 95 and 99 percent levels of confidence.

The degree of correlation at 95 and 99 percent confidence levels was determined for each individual station included in the study. These data are summarized in Table 10. Results of individual station correlation are shown in Appendix H. From the summary (Table 10), it is apparent that suspended solids can be substituted for turbidity measurements, and total coliforms for fecal coliforms with a high level of confidence. Other parameters were not shown to be closely related.

Hourly Variations

One twenty-four-hour study was undertaken on November 6, 1972 from the 7th Street Bridge in Kansas City. Samples were taken every two hours and brought to the laboratory for measurement of the nine parameters in WQI. Data for each individual parameter and the WQI's are listed in Table 11. No significant variations in WQI occurred during this period; however, the data may have been affected by heavy rainfall at 1000, 1200, and 1400 hours and light rain at 1600 and 1800 hours. Flow rate was not measured, thus actual effects of the rainfall are not determined. It is entirely possible that flow patterns for storm water discharge followed the banks too closely for detection at midstream, where samples for this study

were obtained. There is no reason to assume that sampling or analytical errors contributed to the uniform quality reflected in reported WQI.

Transverse and Vertical Variations

On December 5 and 8, 1972, samples were taken from a boat to reflect transverse and vertical variations in Kansas River quality at the Kansas City-7th Street sampling station. A profile of the stream at this station is shown in Figure 10. Sampling sites for both studies are indicated on the profile. Points 1, 3, and 5 are two feet below the water surface. Point 2 is six feet, Point 4 is seven feet, and Point 6 is eight feet below the surface.

On December 5th, beginning at 0830 hours, samples were taken in sequence from each of the six points indicated in Figure 10. A single bottle Dunker sampler, flamed at the inlet tube and in the chamber with a propane torch, was used for sampling. Sampling was repeated at each point in sequence beginning at 1000 hours and again at 1100 hours. Microbiological data obtained from this study are reported in Table 12.

In a similar study on December 8th, two sets of samples were taken at approximately three hour intervals from the same six points, beginning at about 1000 hours. These samples were analyzed for the nine parameters in WQI. Samples for fecal coliforms were taken with a flamed Dunker sampler. Samples for all other parameters were obtained in a Kemmerer sampler and transported to the laboratory in cubitainers. Data from this study are shown in Table 13. Little if any significant change is apparent over the period of observation.

Biological Sampling

At the outset of this project, it seemed desirable to attempt to relate biological data to WQI by installing rock filled sampling baskets at various locations in the stream and observing the diversity of species which collected on the rocks over a period of six weeks. On October 17, 1972, five sets (two each) of baskets were installed: one set in the Kansas River at Lecompton, one at Willard, two at Fort Riley, and one in Soldier Creek. Within the first week, all but two sets, at Lecompton and Willard, were vandalized. These two sets remained intact and were retrieved on November 28th.

The organisms which persisted are identified in Appendix I. The sample size was too small for statistical analysis of species diversity, richness, evenness, redundancy, dominance, etc.; however, the taxa identified can be said to represent a stable community composed of predators, filter feeders, grazers, and other omnivores. The diversity of this community and its food and feeding habits would characterize the following conditions of its aquatic environment:

1) Fairly rapidly moving water (0.6-1.5 ft/sec.) which contains phytoplankton, detached algae, and other suspended materials,
2) Bottom composed mostly of rubble, gravel, and some sand which is covered with periphyton (attached algae) and aquatic moss,
3) Oxygen levels usually above 80% saturation. This is particularly true of water at Willard where three species of stoneflies (Plecoptera) were found. (This group

usually is the first to be eliminated when oxygen concentration is decreased.)

4) Turbidity (silt, shifting sand) relatively low at Willard during this period of observation. Stoneflies (Plecoptera) and mayflies (Ephemeroptera) are well represented.

5) A more stable community at Willard than that at Lecompton, suggesting better water quality at Willard. This observation is supported by WQI(M) calculation reported in Table 6.

APPENDIX I
BIOLOGICAL ORGANISMS
KANSAS RIVER STUDY

Organisms	Lecompton	Willard
Plecoptera		
Aeroneuria sp.		1
Capnia sp.		3
Isogenus sp.	2	15
Ephemeroptera		
Isonychia sp.		9
Paraleptophlebia sp.		2
Stenonema sp.	1	16
Odonata		
Agrion sedula		2
Trichoptera		
Cheumatopsyche sp.	12	14
Hydropsyche sp.	27	30
Smicridea fasciatella	10	8
Coleoptera		
Stenelmis sp.	1	
Diptera		
Ablabesmyia flavifrons		1
Orthocladius nivoriundus		2
Orthocladius sp.	3	23
Simulium vittatum	3	30
Smittia sp. 1		1
Smittia sp. 2		1
Tanytarsus sp.		4
Total number of organisms	59	166
Total number of species	8	17
